A B S T R A C T

Background and Objectives: Evidence indicate relationships between the sunlight exposure, vitamin D status and non-melanoma skin cancer (NMSC) risk. Vitamin D receptor (VDR) polymorphisms have been linked to metabolic changes in insulin resistance and various cancers. The purpose of this study is to investigate relationships between the sunlight exposure and the NMSC risk. Furthermore, relationships between the VDR FokI polymorphism and vitamin D status and the insulin resistance in NMSC patients will be assessed.

Materials and Methods: A hospital-based case-control study is designed. Participants are randomly categorized into case and control groups. Eligible patients are adults who meet the inclusion criteria with verified diagnosis of NMSC with signed informed consents. Totally, 73 NMSC diagnosed cases and 72 healthy controls are recruited and their sunlight exposure data and genetic information are collected via interviews and high-resolution melting (HRM), respectively.

Conclusions: There are controversial reports on the relevance of sunlight exposure to non-melanoma skin cancer risk due to the dual effect of UVB radiation on promoting vitamin D_3 synthesis in the skin and increasing DNA damage leading to skin cancer. Results of this study provide data on how much sunlight exposure includes beneficial health effects with no skin cancer risks. Vitamin D status may affect risks of insulin resistance-linked diseases such as cancers. Findings will contribute to the current knowledge of the roles of vitamin D, insulin resistance and FokI polymorphism in skin cancer development.

Keywords: Vitamin D, Insulin resistance, Non-melanoma skin cancer, FokI polymorphism

Introduction

Non-melanoma skin cancer (NMSC) is the most common increasing type of malignancies in Caucasians worldwide (1). Several clinical and epidemiological studies have demonstrated links between the high ultraviolet (UV) exposure and the skin cancer risk (2). The UV exposure may result in DNA damage in skin cells and is considered as the leading environmental risk factor for all types of skin cancers (3). There are substantial controversies in scientific communities regarding optimum sunlight exposures to set balances between the positive and negative effects of solar UV-exposure (4). It is estimated that nearly half of the populations worldwide are affected by impaired vitamin D status. Strong evidence indicate possible protective roles of vitamin D against cancers, bone fractures, cardiovascular diseases (CVD), autoimmune diseases, type-2 diabetes, influenza and depression (5). Epidemiologic studies support possible protective roles of vitamin D in cancers, including colorectal (6, 7) breast (8, 9), prostate (10, 11), ovarian (12) and kidney cancers (13). However, the association of vitamin D with risk of skin cancer has to be clarified (14). Previous experimental studies have reported possible roles of vitamin D against ultraviolet radiation-induced DNA damage and skin cancer

development (15, 16). The biologically active form of vitamin D, 1,25(OH)2D, or calcitriol, has photoprotective effects and may decrease UV-induced cell death, immunosuppression and mutagenic activity (17).

Vitamin D action is generally mediated by binding to VDR (18). The VDR gene is involved in various pathways including calcium absorption, differentiation and proliferation of immune cells and cellular processes associated with carcinogenesis, such as proliferation, differentiation and apoptosis (19). Up to date, several polymorphisms of VDR have been identified; of which, FokI polymorphism (rs2228570) leads to altered protein structures (20) and subsequent less transcriptional activities (21). Impaired functions of VDR have been associated with increased risks of epidermal carcinogenesis through increasing cellular proliferation and decreasing differentiation of keratinocytes (22). Previous studies have reported conflicting results on whether various VDR polymorphisms can predispose increased risks of NMSC (23–26). The possible negative link between circulating 25(OH)D concentrations and glucose homeostasis including insulin resistance has been suggested in some studies (27, 28). In a prospective study, baseline serum 25(OH)D was inversely associated with 10-year risk of hyperglycemia, metabolic syndrome and insulin resistance (29). It is noteworthy that VDR gene is expressed in adipocytes and pancreatic beta cells; by which, it could affect body composition via directly regulating differentiation and metabolism of adipocytes or indirectly by modulation of insulin (30). However, evidence for the effects of this polymorphism on 25(OH)D concentration, adiposity and insulin resistance in patients with NMSC is rare (31).

Aims and research questions

The current study will address the following questions:

(1) Do NMSC patients have longer duration of occupational direct sun exposure than that unaffected people do?

(2) If yes, does it have any effects on the patient vitamin D status? In other words, do NMSC patients have a higher vitamin D status, compared to that unaffected people do?

(3) Are there any associations between IR and NMSC?

(4) Are there any associations between VDR FokI polymorphism, vitamin D status and NMSC risk?

Hypothesis

The hypothesis describes that people with VDR FokI polymorphism are at increased risk of vitamin D deficiency, insulin resistance and NMSC.

Materials and Methods

Study population

At least 70 patients with skin tumor, including squamous cell carcinoma (SCC) and basal cell carcinoma (BCC), are recruited from dermatology clinics of Razi Hospital, Tehran University of Medical Sciences, Tehran, Iran. Controls consist of 70 age and sex-matched healthy volunteers.

Information and data collection

Subjects are contacted by phone and informed of the study objectives and, if they agree to participate, asked to sign written informed consents. Data on age, sex, education level, marital status, medication and supplement use history, disease history, body mass index (BMI), body fat percentage, blood pressure, sun exposure habits including approximate time of sunlight exposure per day, day period of exposure (morning, noon or afternoon) and sunscreen use. Figure 1 shows the study protocol in brief.

Inclusion/exclusion criteria

Patients are eligible if they are diagnosed with non-melanoma skin cancer within the past three months and are 65 years of age or younger. Participants are excluded from the study if they are taking nutritional supplements such as vitamin D, calcium, omega-3 and antioxidant or medications that modify vitamin D metabolism (corticosteroids, estrogens and calcitonins) for at least three months prior to study and if they have history of other cancers, renal diseases or liver diseases.

Control identification

For every recruited individual, an unrelated healthy age and sex-matched volunteer is recruited from the publicity. The aforementioned exclusion criteria is also used for the control group.

Sample size calculation

Based on the following formula of:

$$n = \frac{(z_{\alpha/2} + z_\beta)^2 \sigma^2 (1 + 1/k)}{\varepsilon^2}$$

$$n = \frac{(1.96 + 0.84)^2 (1 + 1/1)}{0.25}$$

With a power of 80%, a two-sided 5% significant level, expected 25(OH)D concentration in control group ($\varepsilon = \mu_1 - \mu_2$) and effect size of 0.5, a minimum of 59 participants per arm is needed. Therefore, 70 people are recruited to compensate potential losses during the study.

Anthropometric measures and blood pressure

Height is measured to the nearest of 0.1 cm using stadiometer (Seca 216, Seca, Hamburg, Germany). Weight is measured with light clothing and no shoes using digital scale (Seca 808; Seca, Hamburg, Germany) to the nearest of 0.1 kg. The BMI is calculated using the equation body weight (kg) / height^2 (m). Moreover, BMI is majorly categorized as follows: underweight (< 18.5), normal (18.5–24.9) and overweight (> 25.0) according to 2004 World Health Organization (WHO) recommendations. Hip circumference (HC) and waist circumference (WC) are measured using measuring tape to the nearest 0.1 cm. The WC is measured at the approximate midpoint between the lowest rib and iliac crest after a normal expiration. The HC is measured at the level of the greater trochanters. Sitting blood pressure is assessed using digital sphygmomanometer (BC08; Beurer GmbH, Ulm, Germany). All assessments and assessments are carried out by trained nutritionists.

Blood samples

After 12–14 h of fasting, 10 mL of venous blood are collected by expert phlebotomists. After centrifugation, serum is separated and then aliquoted and stored at -80 °C until use. Serum markers include 25(OH) vitamin D, intact parathyroid hormone (iPTH), insulin, fasting serum glucose (FSG) and lipid profiles of triglyceride (TG), low-density lipoprotein-cholesterol (LDL-C), high-density lipoprotein-cholesterol (HDL-C) and total cholesterol (TC). Fasting whole blood samples are collected from all participants for DNA genotyping. The extracted DNA integrity and purity are checked using NanoDrop Spectrophotometer (Thermo-Fisher Scientific, USA) by measuring ratio of the absorbance at 260 and 280 nm. Then, DNA extracts are stored at -20 C° until further genotyping analyses.

Glycemic status and lipid profile

Briefly, FSG and components of lipid profile are analyzed using enzymatic colorimetric methods (Pars Azmoon, Tehran, Iran). Serum insulin is assessed using enzyme immunoassay (EIA) kit (Demeditec Diagnostics GmbH, Kiel, Germany). Homeostasis model assessment of insulin resistance (HOMA-IR) is used as an index of insulin resistance and is calculated using the following formula (32):

HOMA-IR = [fasting insulin (mU/mL) × fasting glucose (mg/dL)] / 405

Serum calcidiol and iPTH assessments

Serum 25(OH)D and iPTH are assessed using EIA kits (Euroimmun, Medizinische Labordiagnostika AG, Germany). Participants are categorized as normal when their total 25(OH)D concentrations are equal to or exceed 30 ng/mL, whereas insufficient and deficient participants have 25(OH)D levels of 20–29 or less than 20 ng/mL, respectively (33–36).

DNA Extraction and Genotyping

PrimePrep Genomic DNA Isolation Kit (GeNet Bio, Daejeon, South Korea) is used for the extraction of genomic DNA, according to the manufacturer's instruction. For VDR FokI polymorphism **(rs2228570),** the forward primer is 5'-GTCAAAGTCTCCAGGGTCAG-3' and the reverse primer is 5'-GCCTGCTTGCTGTTCTTAC-3'. High-resolution melting (HRM) assay using StepOnePlus Thermal Cycler (Applied Biosystems, Foster City, USA) is used for genotyping. The PCR reactions are prepared in a final volume of 20 μL using 5× Hot FIREPol HRM Mix (HRM PCR buffer, HotStarTaq Plus DNA polymerase, nucleotides and EvaGreen dye), 0.3 nM (final concentration) of each forward and reverse primer and 30 ng of DNA. The PCR conditions are as follows: initial denaturation-activation step at 95 °C for 15 min, followed by 40 cycles (denaturation at 95 °C for 15 s, annealing at 61 °C for 20 s, 72 °C for 20 s) and a HRM step from 60 to 95 °C rising at 0.1 °C/s. Curves for each duplicate are checked on the shape and peak height to meet reproducibility. Normalized and temperature-shifted melting curves from HRM (suggestive of SNP) are distinguished. Direct Sanger sequencing is used to verify genotyping results.

Statistical analysis

Mean ±SD (standard deviation) and frequencies are used to express continuous variables and categorical variables, respectively. Kolmogorov-Smirnov test is used to test normality. Comparisons between the groups are carried out using Mann–Whitney, independent samples t-test and chi-squared test when appropriate. Furthermore, ANOVA or Kruskal-Wallis test is used for the comparison of means of variables in various polymorphism groups, for data with normal or abnormal distribution, respectively. For multiple comparisons, Tukey's HD correction is used. Association of the VDR genotype with the risk of skin cancer is estimated by computing the odds ratios

(OR) and 95% confidence intervals (95% CI) using logistic regression analysis. Hardy-Weinberg equilibrium (HWE) is tested using goodness-of-fit chi-squared test to compare the genotype frequencies with the expected frequencies in controls. The statistical analyses are carried out using IBM SPSS Statistics v.23.A (IBM Analytics, USA). Two-tailed values of less than 0.05 are considered statistically significant.

Discussion

In this study, a protocol is described for the case-control studies to show if there are relationships between the VDR-FokI polymorphism and vitamin D and the insulin resistance in non-melanoma skin cancer (NMSC) patients. The study demonstrates the potential functions of VDR in assessment of body composition, glucose homeostasis and mechanism of insulin release. Therefore, genetic variations in VDR genes may contribute to pathogenesis of the metabolic syndrome (37). There are limited data on associations between the Mets and the NMSC risk. Mechanisms, through which it may alter skin carcinogenesis, have not been described yet (38, 39). To the best of the authors' knowledge, this will be the first report on possible associations between the Fok-I VDR gene polymorphism and the IR in NMSC populations. Thus, providing information on the effects of MetS components and vitamin D status in improvement of skin conditions such as NMSC will contribute to development of guidelines for the individuals who are at risk of NMSC.

Ethics and dissemination

Written informed consent will be obtained from the eligible patients prior to participation in the study. Ethical approval will be received from the Ethics Committee of the National Nutrition and Food Technology Research Institute (NNFTRI), Shahid Beheshti University of Medical Sciences (SBUM), Tehran, Iran.
