ABSTRACT

Background and Objectives: Preparation and evaluation of nanocomposite films have become prevalent in recent years. One of the most important methods for dispersing nanoparticles in polymers is the use of ultrasound radiation. Polyvinyl alcohol-montmorillonite (PVA-MMT) nanocomposite films were prepared via solvent casting method.

Materials and Methods: The effects of different ultrasound times (0, 10, 20, 30, and 40 min) on the properties of nanocomposite films were evaluated in a completely randomized design (CRD) with five treatments and three replicates. The films were characterized by mechanical properties, opacity, water vapor permeability (WVP), and color. Fourier transform infrared (FTIR) and X-ray diffraction (XRD) were applied to investigate and prove the effects of ultrasound time.

Results: Results revealed that the ultrasound time significantly affected the characteristics of the films. XRD and FTIR results were in accordance with the effects of sonication time. The changing trends of PVA film properties due to increasing the sonication times were not similar. Sonication time did not have any significant effect on some traits like a^* , WVP, L^* , and yellowness index (YI), while it affected b^* , tensile strength, and opacity significantly.

Conclusions: Depending on the target of using nanocomposite films, appropriate time of sonication should be used.

Keywords: Ultrasound time, Polyvinyl alcohol, Nanocomposite film, Nanoclay, FTIR, X-ray

Introduction

Since 1970, the production and use of plastics in the world have been extensively increased. Waste disposal problems have pushed studies toward the development of polymers that could be degraded more rapidly in the environment (mineralization or bioassimilation). Designing, synthesizing, and using biodegradable polymers, especially natural ones, offer a possible alternative to these non-biodegradable materials, in particular when their collection and processing are not possible and economical (1, 2). The most important barriers in applying biodegradable natural materials, especially for packaging, are their poor mechanical, thermal, and moisture resistance properties. Recently,

nanocomposites such as polymer-layered silicate have become prevalent. Silicate layers should have at least one dimension of less than 100 nm (3-5). MMT is a type of silicate clay that has been widely used in polymer nanocomposites. High intercalation chemistry, strength, abundance in nature, low gas permeability, safety, and economic properties of MMT have led to the widespread use of this material (6-9).

Many investigations have shown that incorporating nano-scaled silicate layers into polymers increases their mechanical properties, heat, and moisture resistance, and also decreases their moisture adsorption, permeability, and flammability (8, 10).

Depending on silicate dispersion, two types of nanocomposite, i.e. intercalated and exfoliated, can be obtained. The latter is known as *delaminated silicate*, and is preferred to the former because of having better barrier and mechanical properties (3, 8, 9, 11, 12).

Producing clay nanocomposites can be usually achieved by 3 methods: *in situ* polymerization, melt compounding, and solvent blending/casting. Researchers have applied suitable blending methods such as shear, high pressure, centrifuge, and ultrasonication mixing for producing a high performance nanocomposite. Ultrasonication is one of the most important methods for increasing intergallery spacing between silicate layers and dispersing them in the polymers. Ultrasound treatment can help in terms of easily achieving exfoliated clay structure and increasing d-spacing in comparison to non-sonicated samples (13). Furthermore, ultrasonication widely affects the polymer itself and, as a result, changes nanocomposites' properties. So, power and time of sonication are critical, and should be seriously considered in nanocomposite preparations (3, 14-17). Ultrasound treatment induces physical and chemical changes in the substances, which are exposed to ultrasound radiation. Acoustic cavitations, bubbles, and their collapses are the main reasons for these changes. Bubble violent explosion generates extreme temperature and pressure inside the bubbles and solvent. So, the materials in the solvent are disintegrated and several highly reactive radicals would be generated. Several chemical reactions can occur between these active radicals and substances in the medium. Finally, more chemical bonds like H and covalent bonds will be generated (16, 18).

Alshabanat et al. found that increasing the sonication time in polystyrene resulted in the creation of crystalline structures in the amorphous region. The maximum peak intensity in the XRD was obtained after 1h of sonicating polystyrene- MMT nanocomposite, which showed higher interaction and chemical bonds with MMT (3). Intergallery spacing of epoxy-clay nanocomposite increased with increasing the sonication time at low clay loading (2%). Dispersion of nanoclay at high sonication times was significantly better. Increase of sonication time enhanced tensile strength, while hardness did not change (15). Chen et al. revealed that 15 min ultrasound time could break cross-links between

amylose and amylopectin in maize starch, which in turn caused depletion in opacity, WVP, elongation in the films, and increased tensile strength (16). Ultrasound and microwave combination, especially lower than 20 min, can significantly affect barrier and mechanical properties of nanocomposite films from methyl cellulose, wheat bran cellulose, and soy protein (17, 19-21). To the best of our knowledge, there are a few reports proving the effects of ultrasound time on preparing popular nanocomposite films like PVA (22, 23).

PVA is a safe and synthetic polymer, which is used widely in industrial, commercial, medical and food applications (24). There are lots of developments in PVA-based nanocomposite films and its blend with starch and other biodegradable polymers. PVA can be employed in food packaging as it shows a broad and universe range of suitable technological properties, as well as user friendly characteristics like low cost and approximate high biodegradation rate (25, 26).

The present research was designed to show and prove the relationship between sonication time and properties of PVA-MMT nanocomposite films, and to illustrate how sonication time will affect nanocomposites' properties. The research was also designed to show the importance of sonication time optimization.

Materials and Methods

Materials: PVA was supplied from LOBA Chemie, Mumbai, India (Polymerization degree: 1700-1800, Viscosity of its 2% solution 25-32 cp, Hydrolysis: 98-99% mole). MMT without any modifications was supplied from Southern Clay Products Inc., USA (Cloisite Na⁺). Glycerol (Pub Chem CID: 753) was purchased from the Merck Company, Germany.

MMT characterizations: Particle size distribution of MMT suspensions was assessed using Malvern Zetasizer, Nanoseries, Nano-ZS (UK). Samples of MMT suspension were collected just before adding it to the polymer solution (Fig.1) and then diluted to proper concentration for analysis by Zetasizer. XRD measurement (X'PertMPD, Philips, Holland XRD) showed the initial space between the silicate layers.

MMT preparation: MMT preparation is illustrated in Fig. 1. All of the nanoclay preparations were carried out in 100 ml laboratory beakers. Stirrers and magnet stirring sets were Heidolf MR 3001 (Germany) and 2 cm magnet, respectively. In nanoclay preparations, a water bath sonicator was

used (ULTRASONS-H, PSelecta CE95, 50 kHz, 1000W). At all stages of nanoclay preparation, the top of the beakers was wrapped tightly with a soft polyethylene sheet to avoid water vaporization.

Film preparation: Each polymer has individual characteristics and the method of film preparation is exclusive. The process of film preparation is illustrated in Fig. 2. In the nanocomposite preparation, stirrer and magnet stirring were Heidolf MR 3001 and 6 cm magnet, respectively. In nanocomposite preparation, a water bath sonicator was used (ULTRASONS-H, PSelecta CE95, 50 kHz, 1000W). From the beginning to the end of nanocomposite preparation, 500 ml blue cap glass containers were used and tightly capped to avoid the solvent evaporation.

Properties of PVA nanocomposite films: The nanocomposite films were characterized by mechanical properties (tensile strength and elongation at break), opacity, WVP, color, YI, and thickness. XRD was used to investigate the dispersion of MMT

in PVA polymer. FTIR spectroscopy was applied to show chemical bonds and the interaction between MMT and PVA/glycerol at different sonication times.

Mechanical properties: Tensile strength and elongation at break evaluations were performed using a texture analyzer (Instron, Hounsfield H50KS, England) according to ASTM D882-12 (27). Speed of upper Instron's jaw was 50 mm/min. Rectangular strips (8*1 cm) were cut from the film sheets, and 2 cm from the top and bottom of the strips was carefully wrapped using adhesive paper scotch. The latter was done to avoid compression, rupture, and slipping of the films between the Instron's jaws. The distance between the jaws was 4 cm. The strips were equilibrated at 25 °C and 50% RH for 72 h before doing the test.

Initial Young's modulus or modulus of elasticity was calculated from the slope of the initial linear region of the stress-strain curve at very small strain or elongation at break (28).

Figure 1. Nanoclay preparation

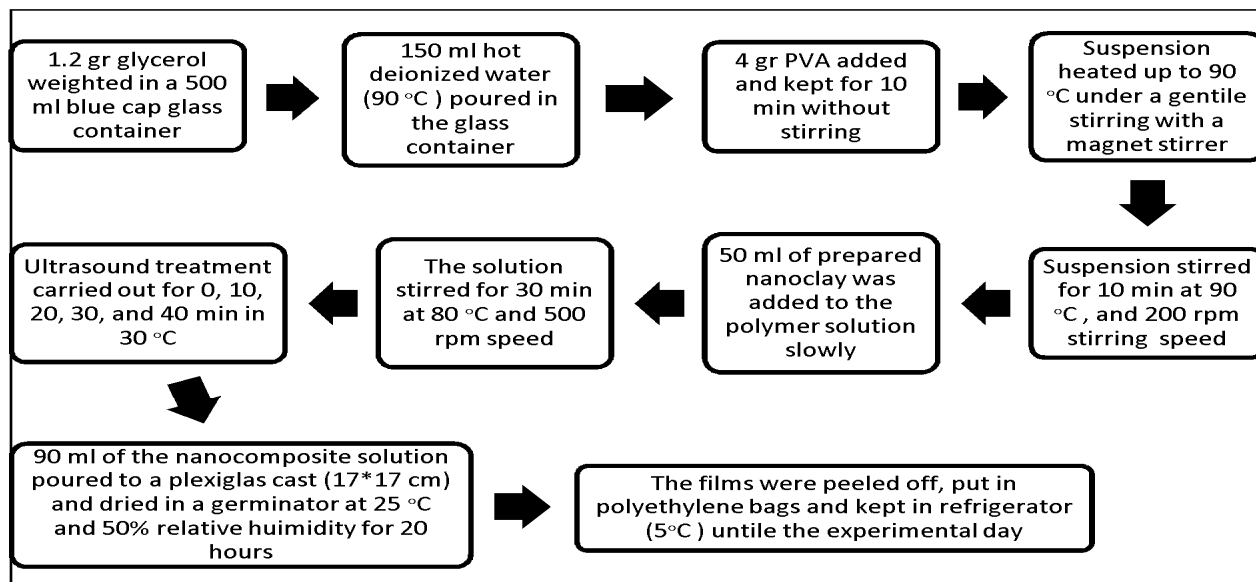

Figure 2. Preparation of PVA nanocomposite films

X-ray diffraction (XRD): Exfoliate and intercalate structures of PVA nanocomposite films were evaluated using X'PertMPD, Philips, Holland XRD, diffractometer equipped with CO K α 1.79 °Å (scanning rate of 0.02°/S, scan step time of 2s, voltage of 40 kv, and current of 30 mA). Data collection was done at 2 θ angle from 1 to 12°.

The XRD software calculated the d-spacing of MMT layers based on Bragg equation (29):

$$\lambda = 2d \sin \theta \quad (\text{Eq. 1})$$

Where, λ is wavelength of the X-ray beam (nm), d is spacing (nm) between the two layers, and θ is the angle of incidence.

Fourier transform infrared spectroscopy (FTIR): FTIR spectra were collected using FTIR spectrometer (Nexus 6700, Thermo Nicolet, USA). Transmission method was applied to the nanocomposite films. IR absorption spectra of the nanocomposite films were obtained for the purposes of measuring and scanning. The spectral collections were performed in the wavenumber range of 400–4000 cm⁻¹ with the resolution of 4 cm⁻¹.

Opacity: Opacity of the nanocomposite films was measured using a Cary 60 UV/VIS spectrophotometer (USA). Rectangular pieces of the films were prepared and put in the sample position of the spectrophotometer. Empty measurement was used as the reference. The opacity of the films was calculated as below (8, 30, 31):

$$\text{Opacity} = \frac{\text{Abs}_{600}}{X} \quad (\text{Eq. 2})$$

Where, Abs_{600} is absorbance at 600 nm, and X is the thickness (mm) of the films.

Water Vapor Permeability (WVP): The WVP evaluations were based on the modified ASTM E96/E96 M-14 method (32). Before running the test, the circle samples (19.625*10⁻⁴ m² in the surface area) were cut and equilibrated at 25°C and 50% RH for 72 h. Then they were carefully placed and sealed using grease oil on the top of the glass cells (7.065*10⁻⁴ m² in the internal surface area, 19.625*10⁻⁴ m² in the edge surface area, and 3.5 cm depth), which contained 8 ml saturated NaCl (74% RH). To prevent the leakage of moisture through the seals, in addition to using grease oil, circle rubber rings were put on the films as well as on the edges of the cells and tightly gripped by 4 metal clamps. The glass cells were put in a desiccator containing 800 gr silicagel at 25°C and 50% RH. The

cells were weighed every 5 h for 72 h. WVP was calculated as follows:

$$WVP = \frac{\Delta m \times X}{A \times \Delta t \times \Delta p} \quad (\text{Eq. 3})$$

Where, WVP is water vapor permeability (gr/m.hr.Kpa), Δm is total weight loss of the cells (gr), X is the thickness of the films (m), A is internal or exposed area of the film (m²), Δt is time of vapor penetration (hr), and Δp is pressure gradient ($\Delta p = 2.368$ Kpa was calculated using a psychrometric chart from Universal Industrial Gases, Inc, Pennsylvania, USA).

Color evaluations: L*, a*, and b* (mode of CIE) parameters of the nanocomposite films were measured in a tristimulus colorimeter (ColorFlex EZ, Bench top Spectrophotometers, USA). Five replicates were performed for each sample (30).

Yellowness index (YI): YI of the films was measured according to the ASTM standard E313-15 (33). Eq.4 was used for YI calculation:

$$YI = \frac{(C_x X - C_z Z)}{Y} \times 100 \quad (\text{Eq.4})$$

Where, XYZ are tristimulus factors, measured by a tristimulus colorimeter (ColorFlex EZ, Bench-top Spectrophotometers, USA), and C_x and C_z are constants obtained from the ASTM standard E313-15.

Thickness: Using a micrometer (Mitutoyo, Model 0052526, Japan), the thickness of the nanocomposite films was measured. Five locations of the films were evaluated, and the average value was used for each sample.

Statistical design: The nanocomposite films were produced in a completely randomized design (CRD). The treatments were: 0 min of sonication time as control (PVA 0), 10 min (PVA 10), 20 min (PVA 20), 30 min (PVA 30), and 40 min (PVA 40). Design Expert ver.7.0 was used for optimization. Using numerical optimization, first goals for each response were set then the software generated optimal conditions. Data were analyzed mainly in the SPSS software (ver. 20). Other statistical softwares such as MSTATC were also used. Multiple range Duncan's test was preformed for mean comparisons ($\alpha = 0.05$). All experiments and measurements were done with at least three replicates.

Results

MMT characterization: MMT characteristics (Company datasheet, ZetaSizer results, and XRD results) are presented in Table 1. The XRD evaluation showed a peak in 8.7 2 θ , revealing 1.178 nm d-spacing between the silicate layers, which was near the reported d-spacing from the company.

Mechanical properties: Different ultrasound times had insignificant effect on elongation and Young's modulus of PVA nanocomposite films ($p>0.05$), while they had significant effect on tensile strength of the films ($P<0.01$). In comparison to the films without sonication, there was 22.28% enhancement in tensile strength due to applying 20 min of sonication time. Tensile strengths of the films are depicted in Fig.3. Young's modulus and elongation at break are reported in Table 2.

WVP: The effect of sonication time on the WVP of PVA films was not significant ($p<0.05$). The obtained WVP data verifies that the time of sonication did not affect the WVP of PVA films. The results are reported in Table 3.

Optimization: Optimization analysis by design expert software showed that 20 min of sonication time was the optimum treatment (with 68.2% desirability) for using films in food packaging. As the 20 min treatment was optimum, other properties (XRD, FTIR, Opacity, Color, and YI) were evaluated at 10, 20, and 30 min of sonication time. Optimization conditions are depicted in table 4.

O: Omitted Peaks; N: New Peaks

Opacity appearance: Opacity is one of the most important features of the films, especially for food packaging. Ultrasound time had significant effect on the opacity of PVA nanocomposite films ($p < 0.05$). As you can see in Figure 7, sonication for 20 min had the lowest opacity (0.0006) in the PVA films.

Figure 7. The effect of ultrasound time on the opacity of PVA nanocomposite films

Color and YI: Statistical analysis showed that time of sonication did not have any significant effect on L^* , a^* , and YI of the PVA films, while it just affected significantly b^* ($p < 0.05$) (Fig. 8).

Thickness: The average thickness of the PVA films was 61.07 micron. It was not significantly changed in the samples with different times of sonication.

Figure 8. The effect of ultrasound time on b^* factor of PVA films

Discussion

MMT characterization: Zetasizer evaluation demonstrated that zeta potential (ZP), particle size average (PSA), and polydispersity index (PDI) of the MMT suspension (0.4% w/v) were -30.4, 195 nm, and 0.264, respectively.

As reported in Table 1, PSA of MMT suspension was around 195 nm. Because 97.7% of the particles had similar size (260.9 nm), the suspension had high homogeneity. PSA from Zetasizer was nearly 10 times smaller than the value reported by company, which was because of soaking, stirring, and sonication of the treatments in the preparation of MMT (Fig. 1). So, these treatments surely decreased the size of the MMT particles. In compatible with this research, Alshabate et al. (2013) reported that Na-MMT suspension had a wide particle size distribution (three peaks), and around 88.2% of particles had 748.5 nm sizes, which is really more than the size of MMT suspension in the present study (3).

PDI is a dimensionless term for showing the band of size distribution, which usually ranges from 0.05 to 0.7 and, out of this range, especially more than 0.7, indicates that the sample is not probably suitable for evaluation by dynamic light scattering (DLS) technique in Zetasizer. PDI of the Na-MMT suspension in this study was 0.264 (Table 1), which was suitable and in the range (3, 34). ZP is a term that expresses the potential difference between the medium of suspension and the stationary layer of the fluid, which is attached to the dispersed particles. ZP of Na-MMT was -30.4 mv, indicating the moderate stability of the nano-particles (35).

Mechanical properties: As illustrated in Fig. 3, increasing the time of sonication up to 20 min caused enhancement of tensile strength. Then it was decreased at 30 min but not significantly at 40 min. Maximum tensile strength was 50.859 and 49.531 MPa at 10 and 20 min of sonication time, respectively (Fig. 3).

If sonication time and intensity increase more, the polymer and its chemical bonds would be probably decomposed; this will adversely affect its mechanical properties, like what has been seen at 20 and 30 min of sonication time. Several researchers have evaluated the effect of ultrasound radiation on different film properties and observed that tensile strength is improved, while different results are obtained about elongation (16, 17, 28, 36). As shown in Table 2, elongation increases up to 20 min of sonication and then decreases. The maximum elongation (141.07%) and tensile strength (50 MPa.) are related to 20 min of sonication; also the minimum Young's modulus (2.15 MPa.) was also corresponded to 20 min sonication (Table 2). Wang et al. (2014) and Cheng et al. (2010)

announced that increasing the time of sonication increased tensile strength up to a certain time, and decreased elongation. In the present study, this trend was expected but we observed that both tensile strength and elongation increased. Other papers have not used glycerol or other plasticizers. The hydroxyl groups of glycerol can attach to PVA by creating new H-bonds, and as a result, elongation will increase. The effect and role of glycerol might be a reason for obtaining the unexpected trends in this study, however, further experiments are needed to prove it. Lui et al. (2004) announced that both tensile strength and elongation of peanut protein films decreased by increasing the time of sonication. It shows that the effects of sonication time could be different depending to the material and formulation.

Mondal et al. (2013) announced that the tensile strength and elongation of PVA with 8% Na-MMT was 54.95 MPa and 160%, respectively. The reported values were near to those of the present research (29). The same results were also reported about the mechanical properties of PVA nanocomposites by Lui et al. (2014) (37). Chang et al. (2003) reported lower and higher elongation (9%) and tensile strength (160 MPa.), respectively (38). The reason of these differences could be related to PVA characteristics, especially the degree of polymerization and formulation of nanocomposites, which can extensively affect mechanical properties of the films.

If the solvent is water, usually active H and OH radicals and hydrogen peroxide will be generated. Several chemical reactions occurred between these active radicals and substances in the medium, like PVA, MMT, and glycerol in the present study. Finally, more chemical bonds (e.g. H and covalent bonds) were generated. Furthermore, sonication causes the exit of air bubble from the solution, which in turn results in more compact films with higher strength and resistance toward elongation (16). All of these mechanisms could be the reasons for improving the tensile strength at higher sonication times in PVA nanocomposites.

WVP: The minimum WVP in PVA films corresponded to 30 min sonication (0.33×10^{-3} gr/m.hr.kpa). The data showed that 30 min of sonication time could decrease just 10.37% of WVP in comparison to the control film. In comparison to other papers, this depletion is low (16, 20). Mondal et al. (2013) reported the WVP of Na-MMT-PVA

nanocomposite films without glycerol as around 0.03×10^{-2} gr/m.hr, which is lower than the obtained value in the present research. As previously described, using glycerol in this research might be the reason of obtaining lower WVP.

X-ray diffraction: Fig.4 shows the X-ray diffraction (XRD) graph of PVA nanocomposite films. At first glance at XRD graph, we can find that the nanocomposites had intercalated structure, as the peak angle of pure MMT decreased from 8.7 to nearly 2 (Table 5) (26). It shows that increasing the time of sonication increased d-space between the MMT layers, and more incorporation of PVA/glycerol between the MMT layers occurred (8, 13).

Intensity/height of the XRD peaks shows the dispersity of MMT layers in the polymers. The lower intensity of the peaks had more scattering of MMT (8). The height of PVA XRD peaks was not noticeably different (Fig. 4), which shows that time of sonication did not have significant effect on the dispersion of MMT in PVA films. As the viscosity of PVA solution was not so high, probably magnet stirring was sufficient for dispersing MMT in PVA solution.

Appearance of nanocomposites: Changing opacity in PVA films did not show any logical trend (Fig. 7). As indicated in Fig. 7, 20 min time of ultrasound had the lowest opacity in comparison to 10 and 30 min. It shows that more air bubbles have been eliminated from the polymer solution at 20 min sonication, and some of the polymer's bonds have break down; therefore, the resulting film has got more transparent (16). In contrast to our expectation, opacity increased at 30 min sonication time, may be due to the formation of new chemical bonds at 30 min sonication time.

Figure 8 shows the trend of changing b^* factor by increasing the time of sonication but the reason is not really obvious. We can just explain that increasing the time of sonication could increase the compactness of the films, so transmittance decreased, and as a result, b^* (Yellow Color) increased. However, this result is not in accordance to the opacity of 30 min sonication time. There are no values and evidences in papers to describe the reasons of obtaining these results, and further researches are needed to clarify the reasons.

FTIR Spectroscopy: Ultrasound treatments caused disappearance of some peaks, and appearance of new ones. Most of the peaks shift positively, and got

sharper with higher intensity. It shows the incorporation of polymer/glycerol into the intergallery spacing of MMT layers and formation of new chemical bonds with MMT layers (3, 20, 39, 40). However, there are not outstanding differences, especially in low wave numbers, between the times of sonication (10, 20, and 30 min). In conclusion, the nanocomposite films should be optimized in terms of sonication to get the best quality. In comparison to methyl cellulose FTIR spectra, in another research by the authors, ultrasound had lower effects on PVA. The reason can be related to low molecular weight and viscosity of PVA in comparison to methyl cellulose. Therefore, the kind of polymer can play a key role in optimization of the time of sonication.

Conclusion: Sonication time remarkably affected the properties of the PVA nanocomposite films. Sonication time can emerge new bonds between polymers and nanomaterials, increase their intensity, and cause more dispersion of nanomaterial in polymer; as a result, properties of the films will be changed widely. Increasing the time of sonication could significantly change tensile strength, opacity, and b^* factor of PVA nanocomposites, while L^* , YI, and WVP did not change significantly. XRD and FTIR verified the effects of sonication time on the films properties. The results of this paper proves the importance and effects of time of sonication on film's traits. By optimizing and selecting appropriate time, the best quality can be achieved.
