A B S T R A C T

Background and Objectives: Regarding the increasing prevalence of metabolic syndrome (MetS), and its association with non-communicable chronic diseases, providing preventive and therapeutic strategies is a priority. A randomized controlled study was conducted to assess the effects of combination therapy of milled brown flaxseed and hesperidin during lifestyle intervention on MetS components.

Materials and Methods: Forty-eight subjects were randomly assigned to receive lifestyle intervention plus combination therapy of brown flaxseed (30 g milled) and hesperidin (two 500 mg capsules) or lifestyle modification alone for 12 weeks. MetS was assessed as a primary endpoint. The trial was registered in clinicaltrial.gov:NCT03737422.

Results: Forty-six percent of patients in the flaxseed-hesperidin group experienced more than three MetS factors improvement from baseline to week 12, while only 17% of patients in the control group fall in this category. A comparison of blood pressure changes throughout the study indicated a greater reduction in blood pressure in the intervention group rather than in the control group (-5.66 *vs*. -1.56 mmHg, $P = 0.049$). The reduction in plasma glucose (-20.35 *vs*. -7.46 mg/dL, $P = 0.007$) and triglyceride (-45.3 *vs*. -8.39 mg/dL, $P = 0.020$) in the flaxseed-hesperidin group was significantly more than the control group after 12 weeks of intervention.

Conclusions: Our results indicate that co-administration of flaxseed and hesperidin as an adjunct to lifestyle modification program is more effective than lifestyle modification alone in the treatment of metabolic syndrome.

Keywords: Metabolic syndrome, Flaxseed, Hesperidin, Lifestyle modification

Highlights

- Supplementing with flaxseed and hesperidin improved more than three factors of metabolic syndrome in 46% of patients.
- Supplementing with flaxseed and hesperidin caused a significant weight loss.
- Supplementing with flaxseed and hesperidin improved systolic blood pressure.
- Supplementing with flaxseed and hesperidin improved glycemic control.

Introduction

Metabolic Syndrome (MetS) is nowadays a serious health problem all over the world (1), as it overlaps with other metabolic disorders, such as diabetes, nonalcoholic fatty liver disease and cardiovascular diseases, while increases the risk of all-cause mortality by 50% (2, 3). Although various definitions have been proposed, the diagnosis of MetS is majorly based on a cluster of abnormal features including central adiposity, glucose intolerance, hypertension, hypertriglyceridemia, and

*Address for correspondence: Zahra Yari. Department of Nutrition Research, National Nutrition and Food Technology Research Institute and Faculty of Nutrition Sciences and Food Technology, Shahid Beheshti University of Medical Sciences, Tehran, Iran. E-mail address: zahrayari_nut@yahoo.com

reduction in high-density lipoprotein (HDL) cholesterol (4). This condition may eventually lead to pro-inflammatory and pro-oxidant states (5-7). Depending on how the syndrome is defined, its prevalence will be different. The prevalence of MetS in Iran is estimated to be above 20%, which have a growing and age-related trend (8, 9).

Lifestyle modification (LSM) including increasing exercise and optimizing dietary composition, along with consumption of functional foods have been proposed as a therapeutic and preventive strategy for MetS (10, 11). Hesperidin and flaxseed have emerged as promising phyto-therapeutic agents, which may exert potential benefits on health mainly through improving the antioxidant status (12), and providing adequate fiber and omega-3 (13-15), respectively. The therapeutic effects of these two compounds on metabolic dysregulation can be attributed to their powerful biological properties on improving lipid profiles (16-18), glucose homeostasis, and insulin resistance (19-22).

Considering lack of data on such combination therapies in patients with metabolic syndrome, we aimed to investigate whether patients following LSM program along with supplementing with 30 gmilled brown flaxseed and one gram hesperidin per day, would have better metabolic parameters compared with those who just follow the LSM program.

Materials and Methods

Subjects

To assess the effects of combination therapy of milled brown flaxseed and hesperidin during lifestyle modification on MetS components, 80 men and women with MetS were recruited from a nutrition and diet therapy clinic affiliated with National Nutrition and Food Technology Research Institute (NNFTRI). For study inclusion, participants were required to be aged 18 to 70 years and diagnosed with MetS based on National Cholesterol Education Program's Adult Treatment Panel III report criteria (23).

The exclusion criteria were any history of cardiovascular, pulmonary, renal, hepatic and gastrointestinal disease. Additionally, taking anti-hypertensive, glucose-lowering medications, lipid modifying agents and omega-3 dietary supplement, being under treatment with steroids and nonsteroidal anti-inflammatory drugs, being on calorie-restricted regimen within 3 months before the commencement of the trial,

being pregnant, lactating were the other main exclusion criteria.

Of the 80 subjects screened, 57 patients including 31 females and 26 males were deemed eligible for inclusion; of which nine were reluctant to participate in the trial. Eventually, 48 patients were enrolled. A flow diagram of the trial is presented in Figure 1. Twenty four patients consumed 30 g/day milled brown flaxseed two 500 mg capsules of hesperidin along with LSM and 24 patients followed LSM program for 12 weeks.
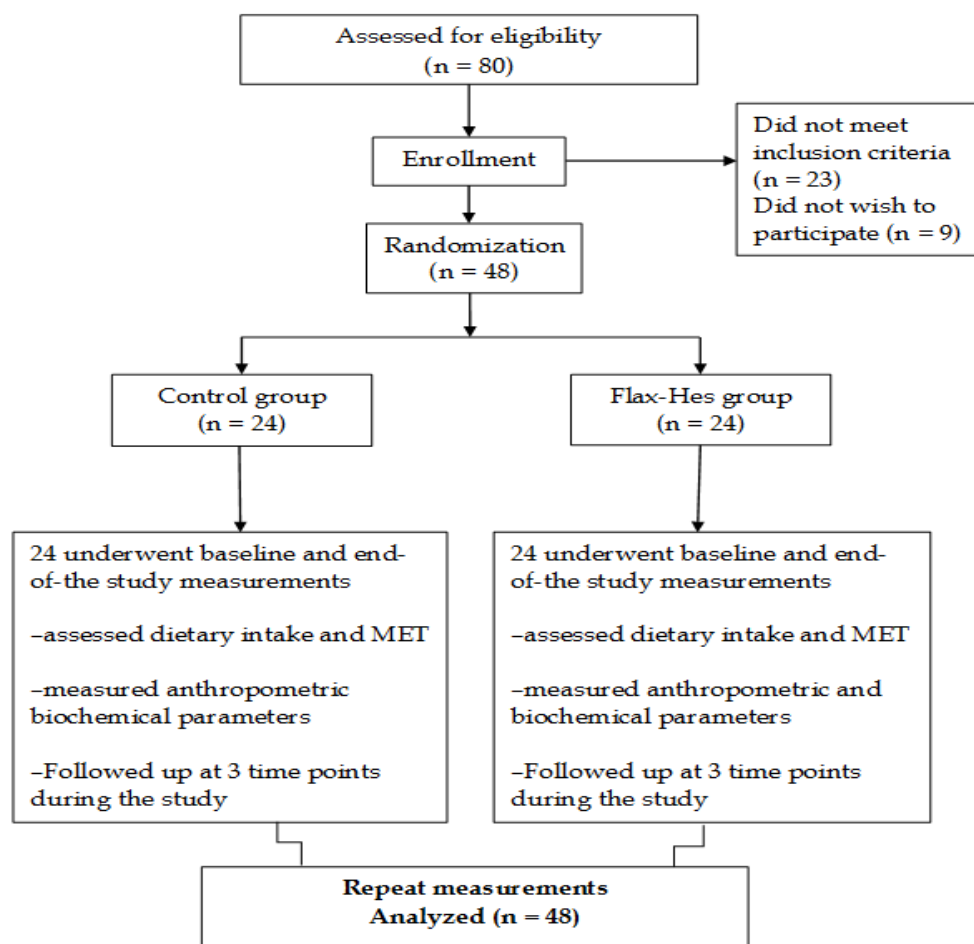

Study design

We conducted a randomized, open labeled, controlled study on patients with metabolic syndrome. The trial was registered with ClinicalTrials.gov, number NCT03737422.

Ethical approval was granted by the Ethical Committee of Shahid Beheshti University of Medical Sciences and all procedures followed were in accordance with the Helsinki Declaration. Participation was voluntary, and all patients provided written informed consent, before beginning the study.

The participants were recruited from advertisement and primary health care centers between January 2018 and July 2018. One of the research assistants who had no other involvement in the trial randomly allocated patients to groups. Since the study was designed as open-labeled, neither patients nor researchers were blind to the interventions. All patients underwent follow-up visits at 4, 8, and 12 weeks after enrolment, at which dietary advice was repeated to patients and adequate supplements were given. Participants were explicitly counseled regarding supplement consumption and how to follow the LSM program, before initiation of the trial.

Supplementation

Each patient was assigned to one of two treatment groups using a table of random numbers for twelve-week intervention of either: 1) lifestyle modification program, 2) lifestyle modification plus combination therapy of brown flaxseed (30 g milled) and hesperidin (two 500 mg capsules). Also, patients were instructed to divide supplements into two equal doses (one capsule of hesperidin and 15 g milled flaxseed), one with breakfast and the other at lunchtime. Hesperidin was 95% pure. The chemical compounds content of flaxseed is well-known. An analysis of brown flaxseed showed about 41% fat, 20% protein, 28% total dietary fiber and 3.4% mineral-rich ash (15).

12

Figure 1. Flow chart depicting the study design

Blood sampling and laboratory tests

Blood samples were collected in the morning after overnight fasting, before and after the intervention, for biochemical measurements. After centrifugation of blood at 3700 rpm for 10 min at room temperature, the separated serum was stored frozen at -80°C until the tests were run.

The levels of serum HDL-C and Triglyceride (TG) were measured by the standard enzymatic method (Pars Azmoon kit, Tehran, Iran). Fasting serum glucose was analyzed by the glucose-oxidase method (Pars Azmoon Co., Tehran, Iran) and serum insulin was determined by enzyme-linked immunosorbent assay (ELISA) (Monobind Inc., USA).

Insulin Resistance was calculatedby using this formula: Fasting Glucose (mg/dl) x fasting Insulin (μU/mL) / 405. Also, the following formula was used to calculate insulin sensitivity:1/ [log glucose (mg/dL) + log insulin(μU/mL)].

Anthropometrics measurements

A clinical evaluation including medical history and clinical data sheet was performed. All participants underwent a detailed anthropometric assessment at the baseline and after completion of the intervention. Height and weight were measured by a trained research assistant based on the standard protocol using calibrated Seca scale with attached stadiometer and recorded to the nearest 0.5 cm and 0.1 kg, respectively. For body mass index (BMI) calculation, weight in kilograms divided by the square of height in meters. Minimum waist circumference was measured with a tape to the nearest 0.5 cm so that we could properly identify subjects who had metabolic syndrome.

Dietary assessment and physical activity

For dietary assessment, we completed three 24-hour food recall questionnaires at the at baseline and after the 12-week study intervention for each patient. Dietary intakes were then analyzed by using the nutritionist version 4 (N4) software. To assess physical activity level, a questionnaire was completed for each patient, which included a list of daily activities, the frequency and time of activities spent per day. Physical activity levels were expressed as metabolic equivalent (METs h/day).

13

Blood pressure

After 15 min of resting, blood pressure was measured twice on the right arm, using a standard mercury sphygmomanometer, at baseline and at 12 weeks. The average of two measurements with at least 10-min interval was recorded.

Data analysis

All analyses were performed using the statistical package for social sciences software (IBM SPSS Statistics for Windows, release 21.0. Armonk, NY, USA: IBM Group). Before further analysis, normal distribution of the variables was checked by applying the Shapiro-Wilk test. Comparison of changes before and after intervention in each group were analyzed by paired t-test. In addition, as appropriate, student's t-test and analysis of covariance (ANCOVA) were applied to assess differences between two groups using baseline value of the outcome, age, sex and mean changes in BMI, MET and energy as covariates. $P < 0.05$ was considered as the significance level.

Results

A total of 80 patients completed the initial screening, of which 32 were excluded due to a lack of interest and failure to meet the entrance criteria. Finally, 48 patients received the allocated intervention. All patients completed a 12-week follow-up program, with an overall intervention adherence rate of 100%. Flow diagram of the study is presented in Figure 1.

As shown in Table 1, there was no significant difference between two groups with regard to baseline characteristics including anthropometric measurements, blood pressure and serum biochemistry tests. There were 25 men (52%), and 23 women (48%) among all participants. The mean age of participants was 44.5 ± 10.7 and 46.7 ± 11.5 in intervention and control group, respectively. No significant differences among the distributions of sex and age between two groups were observed.

Furthermore, data on diet indicated no significant differences in total energy, macronutrients or micronutrients intake between groups. Although the results of the paired t-test revealed a significant decrease in energy intake and macronutrients, except for protein, throughout the study in both groups; but this difference between the two groups was not significant.

A paired t-test was used to compare the changes in each group during the 12-week intervention period. All of the measurements in flax-hes group were significantly improved, except for HDL-C. In control group, in addition to HDL-C, systolic blood pressure and serum triglyceride did not show significant changes (Table 2).

[1] Based on an ANCOVA model that regressed changes from baseline on treatment group, baseline value of the outcome, age, sex and mean changes in BMI, MET and energy.
[2] Paired t-test

The difference of changes between two groups during the interventions were analyzed using ANCOVA adjusted for baseline value of the outcome, age, sex and mean changes in BMI, MET and energy. Mean changes of metabolic characteristics of participants from baseline are presented in Table 2. Anthropometric data comparison between the two groups showed a significant reduction in weight (P= 0.048). With regard to waist circumference, although in the intervention group, Waist circumference (WC) reduction was about twice that of the control group (-6.75 cm vs -3.57 cm), but this difference was not statistically significant.

Comparison of blood pressure changes throughout the study between the two groups indicated a greater reduction in blood pressure in the intervention group, although this difference was only for systolic blood pressure (P = 0.049). Regarding the glucose homeostasis factors, only significant differences were observed in the values of fasting blood sugar (FBS) and quantitative insulin-sensitivity check index (QUICKI). Also, we found approximately near to the significant level differences in HOMA-IR (P = 0.055). However, the changes in insulin levels were fairly similar in both groups (Table 2).

Based on the results presented in Table 2, the reduction in TG was significantly more in flax-hes group than the control group (-45.3 vs. -8.39mg/dL) after 12 weeks of intervention. Although HDL levels increased within both groups, there was no significant difference between the two groups.

After hes-flax consumption, we observed a significant decrease in the number of people with metabolic syndrome. Analysis on MetS factors improvement in response to intervention is presented in Table 3. These results indicate that 46% of patients in the flax-hes group experienced more than three MetS factors improvement from baseline to week 12, while only 17% of patients of the control group fall in this category. As a whole, there was a statistically significant difference between the two groups in terms of changes in MetS from the beginning to the end of the study.

Table 3. Frequency distribution of MetS factors improvement

	Flax-hes group	Control	*P**
No change	3	10	0.023
One factor	4	6	0.477
Two factors	6	4	0.477
≥ Three factors	11	4	0.029

* P values based on Pearson chi squared test

Adverse events and compliance

Patients were instructed to return any unused supplements at every follow up visit. None of the patients had missed more than 10% of the supplements. Also, no complication or serious side effects were observed during the study among the participants that could be attributed to intervention.

Discussion

We found that including daily intake of 30g of whole flaxseed and one gram of hesperidin can modulate metabolic risk factors. Our results indicate that metabolic syndrome was significantly improved over 12 weeks by adding flaxseed and hesperidin to a lifestyle modification program. The combination of hesperidin, as a flavonoid, and flaxseed, as a functional food, can exhibit a great potency in preventing and controlling MetS through their combined anti-inflammatory and anti-oxidant properties as well as high fiber content. Reducing the risk of MetS has been stem from increasing insulin sensitivity, improving dyslipidemia and lowering blood pressure succeeding consumption of flaxseed and hesperidin.

In the present study, although the concentration of HDL did not change, adecline in the concentration of triglyceride was observed in response to hes-flax supplementation. Lack of effectiveness of a lifestyle modification program can be due to a short duration of intervention and lack of complete adherence to the program. These findings are consistent with preceding studies. Administration of 500 mg of purified hesperidin to patients with hypertriglyceridemia markedly reduce serum triglyceride levels over a 24-week period (24), while 800 mg of hesperidin failed to affect plasma HDL-cholesterol after 4 weeks (25). Though in another study, oral administration of 500 mg hesperidin for 3 weeks resulted in a significant increase in HDL, while failed to reduce triglyceride levels (26). One of the proposed mechanisms of the hesperidin effects on lipid profile modulation is through increasing the transcription of the PPAR-α gene (27). In order to achieve significant clinical outcomes, flavonoids should be sufficiently consumed. Moreover, the patient population and length of study are other imperative determinants. In fact, lipid-lowering effects of purified hesperidin should be interpreted with caution as this may not be achievable with usual dietary intake (27).

Flaxseed, in turn, has beneficial effects on lipid profile, which are due to its components specially fiber and omega-3 fatty acids. A recent animal study revealed that adding whole grain flaxseed to the standard rat diet significantly ameliorated the serum levels of TG and HDL-C (28). Also, it was reported in a study conducted on rabbits that supplementation with flaxseed lignans, although could not alter serum triglyceride levels, increased serum HDL significantly (29). High content of flaxseed lignan can reduce triglyceride levels through suppressing the sterol regulatory element-binding proteins (SREBP) mRNA (30). It has been revealed that the hypocholesterolemic effect of flaxseed is more pronounced than wheat in hypercholesterolemic adults, though it led to a slight decrease in HDL-C concentration (31). What seems to have arisen from this study is that fiber alone cannot fully account for all the positive effects of flaxseed in improving the lipid profile. At least part of these beneficial effects is due to omega-3 fatty acids, which has been mentioned in previous studies (32, 33). However, the findings of some studies are inconsistent with these results (34), possibly because the dose or duration of the intervention was insufficient. Since it has been reported that at least consumption of 30 grams flaxseed is required to convert ALA to EPA in young, healthy adults (35).

One of the most remarkable findings of the present study was the improvement of glycemic parameters, including fasting plasma glucose, insulin, HOMA-IR and QUICKI after 12 weeks treatment with combination of hesperidin and flaxseed, which is in line with the findings of most previous studies (36-38). Although no study has evaluated the effects of combination of these supplements, there are several studies that have shown the beneficial effects of each of them alone on glycemic homeostasis. A study by Cunnane et al. reported the hypoglycemic effects of both whole flaxseed and isolated flaxseed fiber (18). Improvementsin either HOMA-IR or QUICKI following flaxseed consumption was described for the first time in 2013 (31). The prominent point of these studies is that flaxseed supplementation can only affect glycemic parameters in interventions duration of at least 12 weeks. The study conducted by Barre and colleagues (39) is in line with this finding, in which 3 months supplementation of flaxseed lignanin patients with type 2 diabetes led to plasma glucose reduction. This was also confirmed in

another study in which flaxseed consumption in patients with MetS could result in blood glucose control and insulin resistance decline after 12 weeks (40). Also, a recently published meta-analysis in this area also indicated this, but with this difference that only whole flaxseed, but not flaxseed oil and lignan extract, has significant effects on controlling glycemic parameters (41). A possible explanation for the necessity of long-term intervention (≥12 weeks) is that improving glucose control and insulin sensitivity require an increase in EPA and DHA concentrations (42, 43) and ALA conversion to these two fatty acids is time-consuming (44). Also, the function of the gut microflora is enhanced gradually by flaxseed fiber consumption, which in turn led to improved blood glucose control and insulin function (45, 46). As well, the higher initial concentration of plasma glucose (>100 mg/dL), the more pronounced changes can be achieved via the flaxseed supplement (41).

According to the Nurses' Health Studies (NHS) I and II, higher urinary excretion of hesperetin is associated with a lower middle- and long-term risk of type 2 diabetes (OR: 0.68) (47). Improving insulin sensitivity and reducing insulin resistance has been stated repeatedly after treatment with hesperidin (26, 36, 48). Increased skeletal muscle glucose uptake has been shown following the positive regulation of insulin signaling by hesperidin. That is why intake of orange juice containing hesperidin following a high-fat and high-carbohydrate meal, prevents increases in the expression of suppressor of cytokine signaling-3, a negative modulator of insulin signaling (49).

Our results demonstrated that patients supplementing with the combination of flaxseed and hesperidin experienced lowered systolic blood pressure after 12 weeks. The anti-hypertensive effect of flaxseed and hesperidin has been shown in previous studies. In the same way, a study conducted in 2015 found that higher urinary polyphenol excretion was allied with lower systolic and diastolic blood pressure, which was attributed to nitric oxide production (50, 51). A meta-analysis of the effects of flaxseed on blood pressure showed that supplementation of various products of the flaxseed can exert beneficial effects on systolic and diastolic blood pressure control (52). This study stated that flaxseed can cause a decrease of 2.85/2.39 mmHg in blood pressure. Since patients with MetS are at high risk for cardiovascular disease, this finding is very valuable. Similarly, Heart Outcome Evaluation study proposed that a 3.3/1.4 mmHg reduction in blood pressure is associated with a 22% decline of relative risk of cardiovascular mortality (53). It is supposed that flaxseed lignan can possess an inhibitory action on angiotensin-converting enzyme (ACE) which results in blood pressure reduction (54). Also, ALA in flaxseed suppresses the soluble epoxide hydrolase activity, which reduces blood pressure through inhibiting the production of inflammatory oxylipins and following vasoconstriction, inflammation and hypertension (55). Although the blood pressure lowering effects of flaxseed have been attributed to fiber and ALA, the exact mechanisms involved in this effect are still not fully understood. Although bioavailability of ALA in whole flaxseed is lower than that of flaxseed oil, whole grain flaxseed has the advantage of providing all bioactive components and fiber with well tolerability (56, 57).

Our study showed significant reduction in weight and waist circumference after 12 weeks supplementation with the combination of flaxseed and hesperidin, although the difference of WC was not significant between two groups, compared to baseline. Studies regarding the effect of hesperidin on anthropometric measures are limited. Supplementation with citrus juice containing vitamin C and hesperidin have no significant effect on weight and WC (48). Therefore, it appears that the weight loss observed in present study is possibly due to the flaxseed, which is in line with previous studies (31, 58). Recent review and meta-analysis study also confirms the positive effects of flaxseedon weight loss, especially if the intervention durations of ≥12 weeks (59). ALA can exert its anti-obesity effects via subsequent converting into long chain poly unsaturated fatty acids in the body (60-62). Furthermore, flaxseed lignans under the gut microflora produced enterolactone, the main component of mammalian lignans, which has been negatively correlated with obesity (63, 64).

The present study does however have its strengths; to the best of our knowledge it is the first interventional study investigating the effect of flaxseed and hesperidin combination as an adjunct to lifestyle modification for the treatment of metabolic syndrome. Although the exact clinical implication of these findings is yet undefined, but could be proposed as a preventive strategy. It needs further studies to explore full potential of flaxseed and hesperidin and confirm these findings.

In conclusion, incorporating 30g of brown flaxseed and one-gram hesperidin into a healthy diet along with increasing physical activity seems reasonable and valuable to reduce risk of MetS through ameliorating insulin resistance, lowering blood pressure, improving glycemic control and modifying lipid profile (15, 65, 66).
